A REVISED SECOND-ORDER DISCRETIZATION
OF THE 2-D ELASTIC BEAM ELEMENT

In the FEM formulation of a plane beam element, the interpolation is improved toward consistency with the beam-column theory. The geometrical effects of the flexural and axial displacements upon the longitudinal strain are explicitly analyzed in up to their second-order terms. The flexural displacement is framed, as usual, in the cubic-polynomial distributions, the magnitudes of which are linear with the nodal parameters. But, in the interpolation of the axial displacement, the secondary effects of the flexural displacement are taken into account, which are expressed in a quadratic form of the deflection parameters.

Key Words: second-order discretization, beam-column theory, interpolation

1. INTRODUCTION

In the recent structural analyses, it seems essential for the elements to be developed into more or less nonlinear stiffness relations. Since an exact solution is difficult in general to be obtained, there have been presented the second-order formulations for various types of elements. Their applications are not restricted only to those problems lying in a range of relatively small displacements. But, truly large displacements can also be dealt with, by their incorporation with the up-dated Lagrangian description or with the method of separation-into-rigid-displacement-and-deformation.

So far as the plane beam element is concerned, since before the age of computational methods, there has been the beam-column theory. In the evolution of matrix methods, the flexural effect of axial force was first estimated by Hertz 3 into the geometrical stiffness matrix. But, as known today, the resulting is a set of linearized relations upon an initial state of axial compression or tension. Nowadays, the second order terms are derived in the following two methods, in principle: One method is to rewrite the slope-deflection equations known in the beam-column theory into a matrix form e.g. 1,2,4,7,8). In this treatment, the flexural effect by an axial force is contained exactly upon the initial state, but the stiffness equation to determine the axial force becomes implicit in terms of the nodal displacements. The other ones are based on the finite element procedure. In the existing formulations for that second-order problem, to be noted, the displacements within an element are still interpolated in a linear form of the nodal parameters e.g. 5,6).

In this study, a revision is presented in the second-order FEM formulation of a plane beam element. The second effect of the beam deflection

* A main part of this paper has been presented at the JSCE Annual Conference 9 held in Nagoya, 1996-9.
onto the axial elongation is exactly taken into account: in the interpolation of the axial displacement, the quadratic terms of the deflection parameters are added to the linear ones. With the use of the same potential energy function, the resulting stiffness relations are consistent with the differential equations in the beam-column theory.

2. KINEMATIC FIELD

Under the Bernoulli-Euler hypothesis, we consider a straight beam deformed in a range of small elastic strains. In the initial state, the spatial $x$-axis is taken onto the centroidal line of cross-section (G-line), with $y$-axis taken parallel to the cross section. The displacement components of that axial line into $\{x, y\}$ are here denoted by $\{u_G(x), v_G(x)\}$. In terms of those components, the axial elongation (a normal component of the Green's strain) is, to be exact, written as

$$ e_{Gxx} = \frac{du_G}{dx} + \frac{1}{2} \left( \frac{du_G}{dx} \right)^2 + \left( \frac{dv_G}{dx} \right)^2 \right) \tag{1} $$

From this expression, where $u_G(x)$ and $v_G(x)$ are independent to each other, the flexural $v_G(x)$ can be larger than $u_G(x)$. The normal strains by the bending (at edges of cross-section) are assumed of the same order:

$$ h \frac{d^2v_G}{dx^2} \simeq \frac{h v_G}{l^2} \simeq \epsilon \tag{2} $$

where $h$ and $l$ are height of cross-section and beam length; and $\epsilon$ is an allowable magnitude of small strains. Eventually, the axial and flexural displacements are related as follows:

$$ \frac{u_G}{l} \simeq \left( \frac{v_G}{l} \right)^2 \simeq \left[ \frac{h}{l} \right]^2 \simeq \epsilon \tag{3} $$

Neglecting higher terms than $\epsilon$ with respect to unity, we have the results well known in the beam-column theory: The displacement components on cross-section are written as

$$ u(x, y) = u_G(x) - y \frac{dv_G}{dx} \tag{4-a} $$

$$ v(x, y) = v_G(x) \tag{4-b} $$

This expression is the same to the small-displacement theory. But, the normal strains on cross-section are given by

$$ e_{xx}(x, y) = \frac{du_G}{dx} + \frac{1}{2} \left( \frac{dv_G}{dx} \right)^2 - y \frac{d^2v_G}{dx^2} \tag{5} $$

We next consider an associated discretization of the beam element, say (e). In terms of its nodal displacements

$$ \{u\}_{(e)} = \{(u, v, \theta)\}_i, \{u, v, \theta\}_j \tag{6} $$

the flexural displacement is interpolated in the same way to the small displacement theory:

$$ v_G(\xi) = \langle \Phi_v \rangle \begin{bmatrix} (v, \theta) \end{bmatrix}_i, \begin{bmatrix} (v, \theta) \end{bmatrix}_j \tag{7-a} $$

$$ \langle \Phi_v \rangle = \begin{bmatrix} 1 - 3\xi^2 + 2\xi^3, l \left( \xi - 2\xi^2 + \xi^3 \right), \end{bmatrix} $$

$$ 3\xi^2 - 2\xi^3, l \left(-\xi^2 + \xi^3 \right) \end{bmatrix} \tag{7-b} $$

where $\xi = x/l$.

In the present kinematic field, however, the flexural $v_G(\xi)$ is relatively large, as given by (3). If this $v_G(\xi)$ takes place with no elongation of the axial line, namely $e_{xx}(x, 0) = 0$ in (5), there must be the axial displacement given by

$$ u_G^e(\xi) = -\frac{1}{2l} \int_0^\xi \left( \frac{dv_G}{d\xi} \right)^2 d\xi $$

$$ = -\left( \langle (v, \theta) \rangle_i, \begin{bmatrix} (v, \theta) \end{bmatrix}_j \right) $$

$$ \left[ \langle \frac{1}{2l} \int_0^\xi \left\{ \frac{d\Phi_v}{d\xi} \right\} \left\{ \frac{d\Phi_v}{d\xi} \right\} d\xi \right] \begin{bmatrix} \langle (v, \theta) \rangle_i, \begin{bmatrix} (v, \theta) \end{bmatrix}_j \end{bmatrix} \tag{8} $$

By the actual integration, the shortening in the entire span is obtained as

$$ \Delta = \frac{1}{2} \left( \langle (v, \theta) \rangle_i, \begin{bmatrix} (v, \theta) \end{bmatrix}_j \right) $$

$$ = \frac{1}{30l} \left\{ 18(v_i - v_j)^2 + 3l(\theta_i + \theta_j)(v_i - v_j) \right\} $$

$$ + l^2(2\theta_i^2 + 2\theta_j^2 - \theta_i \theta_j) \tag{9} $$

On the other hand, in case the axial displacements are fixed at the both ends, for the lateral $v_G(\xi)$, there simultaneously takes place a uniform elongation $\xi \Delta$ to hold the compatibility. As
shown in Fig. 1, by the sum of those second effects onto the linear terms for \( u_i, u_j \), we have the axial displacement interpolated in the following form:

\[
    u_G(\xi) = (1 - \xi, \xi) \begin{bmatrix} u_i \\ u_j \end{bmatrix} + u^*_G(\xi) + \xi \Delta \tag{10}
\]

As the result, in expression (5) for \( e_{xx} \), the \( u^*_G(\xi) \) contained in \( u_G(\xi) \) is canceled by the square term of \( dv_G/dx \). The normal strain on the axial line is given by

\[
    e_{Gxx} = \frac{1}{l} \{ u_j - u_i + \Delta \} : \text{const.} \tag{11}
\]

The normal stress on the axial line is given by

\[
    E \frac{d^2v}{dx^2} = \frac{M}{I} \quad \text{where} \quad \frac{M}{I} = \frac{N}{E} \frac{d^2v}{dx^2}
\]

After interpolation (7) and (10) introduced into (13), the stationary condition for variation \( \delta\{u\}_{(e)} \) is written as

\[
    \delta W = \int_0^1 \left[ \int (v, \theta) \begin{bmatrix} \delta(v) \\ \delta \theta \end{bmatrix} \right] d\xi + \frac{EA}{l} \left\{ \begin{array}{c} u_j - u_i + \Delta \\ \delta u_j - \delta u_i + \delta \Delta \end{array} \right\} d\xi
\]

where \( \delta \{u\}_{(e)} = 0 \)

Substituting the variation of the shortening \( \Delta \) given by (9), by the arbitrariness of \( \delta\{u\}_{(e)} \), we have the following nodal force-nodal displacement relations:

\[
    -F_{xi} = F_{xj} = N \tag{15-a}
\]

\[
    \begin{bmatrix} F_y \\ M \end{bmatrix}_i = \begin{bmatrix} [k_0] \\ N[k_G] \end{bmatrix}_i
\]

\[
    \begin{bmatrix} v \\ \theta \end{bmatrix}_i
\]

where

\[
    N = \frac{EA}{l} \{ u_j - u_i + \Delta \} \tag{16-a}
\]

\[
    [k_0] = \begin{bmatrix} 12 & 6l & -12 & 6l & 4l^2 & -6l & 2l^2 \\ 12 & -6l & 4l^2 & -6l & -6l & 4l^2 & \text{Sym.} \end{bmatrix}
\]

3. STIFFNESS RELATIONS

The axial force and the bending moment in cross-section are related to the displacements of the axial line, as follows:

\[
    N = E \int e_{xx} dA = EA \left( \frac{dv_G}{dx} + \frac{1}{2} \left( \frac{dv_G}{dx} \right)^2 \right)
\]

\[
    M = E \int y e_{xx} dA = -EI \frac{d^2v_G}{dx^2} \tag{12}
\]

The total potential energy of the beam element subjected to external forces \( \{F_x, F_y\} \) and moments \( M \) at the both ends is written as

\[
    W = \int_0^l \left[ \frac{M^2}{2EI} + \frac{N^2}{2EA} \right] dx
\]

\[
    -\left\{ F_x u_G + F_y v_G + M \theta \right\} \bigg|_{x=0}
\]

\[
    -\left\{ F_x u_G + F_y v_G + M \theta \right\} \bigg|_{x=1} \tag{13}
\]

Fig. 1 Decomposition of axial displacement
of element (e):

\[ U_{(e)} = \frac{EA}{2l} (u_j - u_i + \Delta)^2 + \frac{1}{2} \left\{ (v, \theta)_i, (v, \theta)_j \right\} \left[ k_0 \right] \left\{ \begin{array}{c} v \\ \theta \end{array} \right\} \]

(19)

4. NUMERICAL EXAMPLE

A slender beam element is considered: \( l = 500 \) cm, \( E = 2,100 \) tonf/cm², \( A = 26.84 \) cm², and \( I = 151 \) cm⁴. First, with node \( i \) being fixed in a cantilever support, a vertical \( F_{yj} \) is applied up to 1 tonf at the other node (see Fig.2). The resulting displacements \( (u, v, \theta)_j \) are shown in Fig.3: the lines with symbol □, ○ and △ indicate the present second-order relations; and the plain lines are a result regarded as numerically exact, obtained by the separation method with a segmentation into ten elements.

Next, after subjected to a preceding axial force \( F_{xj} = -1/3 \cdot \pi^2 EJ/l^2 = -4.17 \) tonf, in a simple support, an additional \( M_i \) is applied up to 1,000 tonf-cm at node \( i \) (see Fig.4). The displacements \( (u_j, \theta_i, \theta_j) \) are shown in Fig.5. Those lines of displacements seem lying in a good approximation. But, for example, if \( (u_j, \theta_i, \theta_j) = (-1.23 \text{cm}, 0.139, -0.083) \) obtained at \( (F_{xj}, M_i, M_j) = (-4.17 \text{tonf}, 200, 0 \text{tonf-cm}) \) in the numerically exact analysis are estimated by the second-order relations, the nodal forces are \( (F_{xj}, M_i, M_j) = (-18.6 \text{tonf}, 48.6, 111.7 \text{tonf-cm}) \). If subjected to no axial force, in the same comparison, the nodal forces for \( (u_j, \theta_i, \theta_j) = (-0.55 \text{cm}, 0.105, -0.053) \) at \( (F_{xj}, M_i, M_j) = \)
(0.1tonf, 200., 0.1tonf-cm) are approximated by
\((F_{xj}, M_i, M_j) = (0.02\text{tonf}, 200.2, -0.07\text{tonf-cm})\).
In the present stiffness relations, the flexural relations between \((F_y, M)_i, (F_y, M)_j\) and
\((v, \theta)_i, (v, \theta)_j\) are linear for a given axial force. Together with the three straight lines for
\(F_{xj} = -4.17, 0.\) and 4.17 tonf, Figure 6 shows
a curved response of angular displacement \(\theta_i\) in a
loading \((F_{xj}, M_i) = (-4.17, 0.) + \rho(8.34, 1000.), 0. \leq \rho \leq 1.\)

5. CONCLUDING REMARKS

As for a plane beam element, the third-order
terms were already presented in Ref.[10], which
are derived by the perturbation technique applied
to the governing differential equations for truly
large displacements. Within the second-order
terms, the present stiffness relations through (15)
to (19) coincide with the perturbation result. The
second-order relations are usually said valid for
deflection angles less than 10° e.g. 9). But, as
shown in the former example, if subjected to a
certain axial force such as a fraction of the Euler
buckling load, the accuracy is not sufficient. This
defect is, of course, improved by a subdivision
into smaller segments. To derive nonlinear stiff-
ness relations, there might be other preferable
methods for some particular elements, but the
second-order formulation through the FEM
procedure seems a consistent method applicable to a
wide variety of structural elements.

平面はり要素の弾性2次理論としての一離散化展開

阿井 正博・田村 健太郎・西野 文雄

平面はりの弾性2次離散化関係には、はりー柱理論のたわみ公式をマトリックス構造解析用に書き直したものの、および有限要素法の手順によって離散化展開されるものとある。前者は、曲げ変形におよぼす軸力の効果を初期状態まわりで正確に現すと考えられるが、その軸力を節点変位に関しては剛性化で表すことができない。ここでは、後者によるこれまでの結果を視覚しながら、定式化の最初である変位補間式から一貫した2次非線形理論としての展開を示しており、はりー柱理論に整合する1つの離散化結果を得ている。
