We propose a hysteretic model of thin-walled circular steel piers under biaxial bending to predict the ultimate seismic behavior of cantilever-type thin-walled circular steel piers. The proposed pier model consists of a concentrated mass and a rigid bar with multiple nonlinear springs located at the pier base. This multiple spring model is characterized by the point that the hysteretic constitutive relation for each spring is determined by the in-plane behavior of steel piers. Herein, the in-plane behavior of the steel piers is predicted by the existing 2-parameter model. The validity of the proposed model is examined by comparing with the results of the 3D-earthquake response analysis, using FEM shell models.

Key Words: multiple spring, inelastic behavior, local buckling, thin-walled pier, dynamic response analysis

1. INTRODUCTION

Thin-walled steel piers are often used in Japan as elevated highway bridge piers because of their structural advantages, i.e., small cross-sectional area and high earthquake resistance. In the design of these piers, however, the effects of local buckling on their ductility must be carefully considered, as observed in the 1995 Kobe Earthquake⁴ (Fig.1). Since the 1995 Kobe Earthquake, much experimental and analytical research⁵ has been conducted to examine the stability and ductility of thin-walled steel piers under cyclic loading. Based on these research, some single degree of freedom empirical models such as bi-linear kinematic hardening model⁶, 2-parameter model⁷ and damage index model⁸ have been presented to express the in-plane hysteretic behaviors of steel piers in view of the application to the seismic design based on the dynamic response analysis. Since the bi-linear kinematic hardening model ignores the softening behavior due to local buckling, the application of this model is restricted to the region where the local buckling is insignificant. Regarding the other two models⁹, the empirical formulas have been deduced from a lot of experiments and/or FEM analysis results in order to include the...
complicated effects of local buckling and cyclic hardening of steel on the hysteretic behavior of piers. The accuracy of these two models is confirmed by the pseudo-dynamic tests under in-plane strong earthquake excitations\(^6\).

Up to the present, the research work concerning the hysteretic modeling of the steel piers has been mainly restricted to their in-plane behaviors. As observed in the 1995 Kobe Earthquake and the recent experiment\(^6\), however, three-dimensional seismic excitations affect the damage of steel piers. Therefore, it is more desirable to consider the three-dimensional effect in design. For this purpose, it is necessary to develop a three-dimensional hysteretic model that considers the interaction of axial force and bi-axial bending.

Herein, as a three-dimensional hysteretic model for thin-walled circular steel piers, we propose a multiple spring model. This model consists of a concentrated mass and a rigid bar with multiple nonlinear springs located at the pier base. The idea of the multiple spring model is similar to that of the four spring model presented by Lai \textit{et al.}\(^7\) that has been used to express the three-dimensional behavior of reinforced concrete elements, although an elastic bar is used in lieu of the rigid bar. Wada \textit{et al.}\(^8\) also presented a multiple shear spring model for reinforced concrete columns where the number of springs is increased compared with the four spring model and the rigid bar is introduced instead of the elastic bar, similar to our model. But his method to determine the spring parameters is not described in detail and looks very empirical. Recently, Ohi \textit{et al.}\(^9\) developed a four spring model for the steel frames by using the multi-linear skeleton line for spring and introducing a target point concept for the hysteretic rule following the original four spring model\(^7\). However, the calibration of spring parameters is based on the monotonic loading test data due to the lack of the suitable data concerning the hysteretic behavior. Furthermore, the method of determining spring parameters is empirical. Four springs are insufficient to express the homogeneous behavior of circular steel piers in any horizontal directions. Here, we determine the number of springs by examining whether the horizontal homogeneous behavior is ensured. What is most important for the multiple spring model is to determine the constitutive rule for each spring so that the effects of local buckling and cyclic strain hardening along with the \(P-\Delta\) effect can be properly considered. In our model all the springs are assumed to have the same constitutive relations. These constitutive relations are determined by using curve-fitting techniques such that the multiple spring model can best express the in-plane hysteretic behavior of circular steel piers expressed by the existing 2-parameter model.

The accuracy of our multiple spring model is examined by comparing with the 3-D earthquake response analysis results obtained by geometrically and materially nonlinear FEM shell elements\(^10\). In this FEM analysis, the three-surface model\(^11\) is used as a cyclic plasticity constitutive model for steel. The proposed multiple spring model is intended to express the hysteretic behavior of thin-walled circular steel piers with constant cross-section. However, as long as the localized deformation occurs in a single location, some minor modification may make it possible to apply the present model to steel piers with variable cross-section.

2. MULTIPLE SPRING MODEL

The pier is modeled by a rigid bar with multiple springs located on the middle surface of the thin-walled circular pier, as illustrated in Fig.2. Spring \(1\) and spring \(m_2\) are located on the \(X\)-axis, whilst spring \(m_1\) and spring \(m_3\) are on the \(Y\)-axis. It is assumed that no horizontal relative displacement occurs at the base of the pier. Springs are arranged with equal intervals along the middle surface of the thin-walled circular cross-section. Furthermore, the locations of the respective spring are so arranged that they become symmetric with respect to both \(X\) and \(Y\) axes.

From the kinematic relation, the incremental vertical displacement of the \(i\)-th spring \(\Delta d_i\) is expressed as

\[
\Delta d_i = -\frac{R}{L} (\Delta D_x \cos \theta_i + \Delta D_y \sin \theta_i) + \Delta D_z \quad (1)\]

\(2(1 \times 25)\)
where \( R \) and \( L \) are the radius and height of the pier; \( \Delta D_x \), \( \Delta D_y \), and \( \Delta D_z \) are three incremental translational displacement components at the top of the pier; \( \theta_i \) is the angle that specifies the location of the \( i \)-th spring (Fig.2).

The moment equilibrium and the vertical force equilibrium at the base of the pier lead to

\[
\Delta F_x = -\frac{R}{L} \sum_{i=1}^{N} \Delta f_i \cos \theta_i 
\]

\[
\Delta F_y = -\frac{R}{L} \sum_{i=1}^{N} \Delta f_i \sin \theta_i 
\]

\[
\Delta F_z = \sum_{i=1}^{N} \Delta f_i 
\]

where \( \Delta F_x \), \( \Delta F_y \), and \( \Delta F_z \) are three incremental force components applied at the top of the pier; \( \Delta f_i \) is the incremental force of the \( i \)-th spring and \( N \) is the total number of springs.

For each spring, the following constitutive relation holds.

\[
\Delta f_i = k_i \Delta d_i 
\]

where \( k_i \) is the tangent stiffness of the \( i \)-th spring. From Eqs. (1)–(5), we can get the following relation of the incremental force-displacement relation at the top of the pier,

\[
\begin{bmatrix}
\Delta F_x \\
\Delta F_y \\
\Delta F_z
\end{bmatrix}
= 
\begin{bmatrix}
a_{11} & a_{12} & a_{13} \\
a_{21} & a_{22} & a_{23} \\
a_{31} & a_{32} & a_{33}
\end{bmatrix}
\begin{bmatrix}
\Delta D_x \\
\Delta D_y \\
\Delta D_z
\end{bmatrix}
\]

where

\[
a_{11} = \frac{R^2}{L^2} \sum_{i=1}^{N} k_i \cos^2 \theta_i
\]

\[
a_{12} = a_{21} = \frac{R^2}{L^2} \sum_{i=1}^{N} k_i \cos \theta_i \sin \theta_i
\]

\[
a_{13} = a_{31} = -\frac{R}{L} \sum_{i=1}^{N} k_i \cos \theta_i
\]

\[
a_{22} = \frac{R^2}{L^2} \sum_{i=1}^{N} k_i \sin^2 \theta_i
\]

\[
a_{23} = a_{32} = -\frac{R}{L} \sum_{i=1}^{N} k_i \sin \theta_i
\]

\[
a_{33} = \sum_{i=1}^{N} k_i
\]

**3. CONSTITUTIVE MODEL FOR EACH SPRING**

(1) General

In the multiple spring model, it is critically important to determine the constitutive relation for springs so that the model can properly express the effects of local buckling and cyclic strain hardening along with the \( P - \Delta \) effect. In our model all the springs are assumed to have the same constitutive relation.

The local buckling occurs only in the location where the axial compressive stress becomes dominant. Therefore, the softening behavior of a spring is considered only on the compression side. The shape of the skeleton curve adopted here is shown in Fig.3. The tension side of the skeleton curve is expressed by the bi-linear curve while the compression side is by the tri-linear one with a descending part that represents the strength deterioration due to local buckling. In determining the model parameters for the skeleton curve of the spring, we use two-step process. First, we assume that the tension side of the skeleton curve is the same as the compression side. Then, the model parameters are determined by curve fitting technique, using the FEM results with beam elements where the local buckling effects are ignored. Second, the compression side is determined on the basis of the 2-parameter model’s empirical in-plane skeleton curve that takes into account the local buckling effect.

As for the hysteretic rule for each spring, we adopt the basic idea of the 2-parameter model and present a new hysteretic rule.

(2) Determination of tension side of skeleton curve

The skeleton curve of a spring (Fig.3) reflects the behavior of piers. When some parts of pier are subjected to axial tensile stress, local buckling will not occur in these parts. So the tension side of skeleton curve is assumed to be bi-linear type without considering buckling. To determine the parameters of the bi-linear model, we use monotonic
in-plane horizontal force-displacement relation at the top of the pier that is given by FEM analysis with beam element. In such FEM analysis, local buckling effects are excluded but the material nonlinearity of steel is considered by the uniaxial constitutive model of steel as shown in Fig. 4. For simplicity, the vertical force is assumed to be zero and only the horizontal force is applied. This assumption is valid since the geometrical nonlinearity due to the $P-\Delta$ effect is taken into account when we determine the compression side of the skeleton curve as explained later in 3. (3).

From the analysis results of several piers, it is found that the horizontal force-displacement relation at the top of pier can be well approximated by a bi-linear curve, as illustrated in Fig. 5, where the intersection point $Y$ of the two sublines are in the following

$$F_{xy} = 1.2 F_{xy0} = 1.2 \frac{\sigma_y I}{L(R + t/2)} \quad (13)$$

$$D_{xy} = 1.2 D_{xy0} = 1.2 \frac{F_{xy0}}{K_{xx}} \quad (14)$$

where $F_{xy0}$ and $D_{xy0}$ are yield horizontal force and yield horizontal displacement of pier without vertical force obtained by the beam model; $\sigma_y$ is the yield stress of steel; $I$ is the second moment of inertia; $L$ is the height of the pier; $R$ and $t$ are the radius and the thickness, respectively, of the thin-walled circular steel pier; $K_{xx}$ that is the initial elastic stiffness is given as

$$K_{xx} = \frac{1}{\frac{L}{3E} + \frac{L}{GAx}} \quad (15)$$

respectively, of the thin-walled circular steel piers. The secondary tangent stiffness is

$$K_{xx} = 0.04 K_{xx} \quad (16)$$

The coefficients 1.2 and 0.04 in Eqs. (13), (14) and (16) are determined based on the results of our FEM analyses by ABAQUS[10]. These values are identified in the present research.

Finally, the monotonic horizontal force-displacement relation of the pier with beam model is expressed as

$$F_x = \begin{cases} 
K_{xx} D_x & (0 \leq D_x \leq D_{xy}) \\
F_{xy} + K_{xx} (D_x - D_{xy}) & (D_{xy} < D_x) 
\end{cases} \quad (17)$$

Based on the force-displacement curve of the pier expressed by Eq. (17), the parameters of the skeleton curve on the tension side of the spring model (Fig. 3) are obtained. Herein, the horizontal force is applied in the $X$ direction. From Eq. (6), the incremental in-plane ($X-Z$ plane) force-displacement relations are derived respectively as

$$\Delta F_x = a_{11} \Delta D_x + a_{13} \Delta D_z \quad (18)$$

$$\Delta F_z = a_{13} \Delta D_x + a_{23} \Delta D_z = 0 \quad (19)$$

When we determine the elastic constant $k_{se}$ of the spring, $k_1$ can be taken as constant, that is, $k_1 = k_{se}$. Furthermore, a fully plastic state can be assumed to determine $k_{zp}$, because the monotonic horizontal force-displacement relation is approximated by the bilinear curve where the secondary line corresponds to the fully plastic state. Therefore, in both cases to determine stiffness $k_{se}$ and $k_{zp}$, $k_1$ can be assumed constant and Eqs. (18) and (19) can be rewritten as

$$\Delta F_x = k_{b1} \Delta D_x - k_{b3} \Delta D_z \quad (20)$$

$$\Delta F_z = -k_{b3} \Delta D_x + k_{b3} \Delta D_z = 0 \quad (21)$$

where $k$ is the tangent stiffness of the springs that
becomes \( k_{\text{el}} \) in the elastic range and \( k_p \) in the plastic range; 
\[
b_{11} = \frac{R^2}{L^2} \left( \sum_{i=1}^{N} \cos^2 \theta_i \right) ; \]
\[
b_{13} = b_{31} = \frac{R}{L} \left( \sum_{i=1}^{N} \cos \theta_i \right) \quad \text{and} \quad b_{33} = N . \]
It should be noted that \( \sum_{i=1}^{N} \cos \theta_i = 0 \) when the springs are located symmetrically with respect to the Y-axis. Therefore, Eqs. (20) and (21) are reduced to
\[
\Delta F_x = k_{e1} \Delta D_x \quad (22) 
\]
\[
\Delta D_z = 0 \quad (23) 
\]
Eq. (22) is used to determine two of the parameters of spring: the elastic tangent stiffness \( k_{e} \) and the plastic tangent stiffness \( k_p \)
\[
k_{e} = \frac{k_{xe}}{b_{11}} \quad (24) 
\]
\[
k_p = \frac{k_{xp}}{b_{11}} \quad (25) 
\]
The intersection point \( t_r \) \( (d_r, f_r) \) of the two sublines of the bi-linear spring model on tension side is determined by a trial and error method such that the final elasto-plastic range of monotonic loading curve by multiple spring model may coincide well with the bi-linear horizontal force-displacement curve of a pier determined by FEM beam analysis as shown in Fig.5.

If we assume a value of \( d_r \), a monotonic horizontal force-displacement curve can be calculated by the multiple spring model. Fig.6 shows a comparison between the bi-linear model and the horizontal force-displacement curve obtained by the multiple spring model. It is observed from Fig.6 that the stiffness of monotonic loading curve by the multiple spring model decreases gradually after yielding and approaches to a final value corresponding to a fully plastic state. \( a \left( D_{xa}, F_{xa} \right) \) is a point on the secondary line of the bi-linear model of a pier. \( a_s \left( D_{xa}, F_{xa} \right) \) is a point on the monotonic horizontal force-displacement curve by the multiple spring model, where \( D_{xa} = D_{xa} \cdot D_{xa} \) is a relatively large value that represents almost a fully plastic state. As illustrated in Fig.6, the optimum value of \( d_r \) exists somewhere between \( d_{r,\mu} \) and \( d_{r,\nu} \). The following can be given as initial limiting values for the bisection iterative method:
\[
d_{r,\mu} = 0 \quad (26) 
\]

\[\text{Fig.6 Determination of tension side of skeleton curve}\]

\[
d_{r,\nu} = \frac{R}{L} D_{xy} \quad (27) 
\]
where \( D_{xy} \) is the horizontal coordinate of the intersection point \( y \) of the bi-linear pier model as shown in Fig.5. Eq. (27) corresponds to the displacement of the outermost springs when the horizontal displacement at the top of the pier reaches \( D_{xy} \). As is clear from the bi-linear approximation shown in Fig.5, the yielding of multiple spring model starts at the outermost springs under the horizontal displacement smaller than \( D_{xy} \). Thus, \( d_{r,\nu} < \frac{R}{L} D_{xy} \).

Once the initial range of \( d_{r,\nu} \) is identified, the usual bisection iterative method is used to determine the optimum value of \( d_{r,\nu} \). After \( d_{r,\mu} \) is obtained, \( f_r \) is given by
\[
f_r = k_{p} d_r \quad (28) 
\]
The tension side of the skeleton curve is finally determined as
\[
f = \begin{cases} 
    k_{\nu} d_r, & (0 \leq d < d_{r,\nu}) \\
    f_r + k_{p} (d - d_{r,\nu}), & (d_{r,\nu} \leq d)
\end{cases} \quad (29) 
\]

(3) Determination of compression side of skeleton curve

After the tension side of the skeleton curve is determined, we proceed to identify the compression side. Herein, the empirical in-plane skeleton curve of the 2-parameter model\(^{11}\) illustrated in Fig.7 is used as a basis for our curve fitting. The 2-parameter model is an evolutionary-degrading restoring force model developed for thin-walled steel bridge piers. In this model the following three non-dimensional quantities\(^{12}\) are used as governing parameters for
thin-walled circular steel piers: the radius-to-thickness ratio parameter \( R_t \); the slenderness ratio parameter \( \lambda \) and axial force ratio \( \mu \).

\[
R_t = \frac{R \sigma_y}{t E} \sqrt{3(1-v^2)}
\]

\[
\lambda = \frac{2L}{r} \pi \frac{\sigma_y}{E}
\]

\[
\mu = \frac{P}{\sigma_y A}
\]

where \( R \) and \( t \) are the radius and the thickness, respectively; \( \sigma_y \) is the yield stress of steel; \( E \) is the Young's modulus; \( v \) is the Poisson's ratio; \( L \) is the height of the pier and \( r \) is the radius of gyration of the cross-section; \( P \) is a constant vertical compressive load acting on the top of the pier; \( A \) is the cross-sectional area of the pier.

As can be seen from Fig.7, the skeleton curve of the 2-parameter model is uniquely determined by the yield point \( y (D_{xy}, F_{xy}) \), the maximum point \( m (D_{x_m}, F_{x_m}) \) and the softening stiffness \( K_s \). The details of how to determine these quantities in terms of the governing parameters \( R_t \), \( \lambda \) and \( \mu \) are explained in Refs. 4), 12) and 13). Here we only show the parameters of this model

\[
\frac{F_{x_m}}{F_{xy}} = \frac{0.02}{(R \lambda)^{0.8} + 1.10}
\]

\[
\frac{D_{x_m}}{D_{xy}} = \frac{1}{3(R \lambda^{0.5})} \frac{2}{3}
\]

\[
\frac{K_s}{K_1} = -1.41 R_t (1 + \mu)^{5 \lambda^{1.5}}
\]

where \( F_{xy} \), \( D_{xy} \) and \( K_1 \) are obtained from the elastic theory.

Based on the 2-parameter model, we now try to determine the parameters of the tri-linear skeleton curve concerned with the compressive behavior of the spring as shown in Fig.3. The skeleton curve of the spring under compressive force is composed of elastic line, hardening line and descending line. The tangent stiffness of the three lines are expressed by \( k_{se} \), \( k_{sh} \) and \( k_{sd} \). Two intersection points of the tri-linear curve is denoted by \( c_y (d_s, f_s) \) and \( c_m (d_m, f_m) \). Among these parameters, five are independent and must be determined.

The stiffness of the elastic line can be assumed to be the same as the tension side

\[
k_{se} = k_{se}
\]

It may be assumed that the yield point \( y (F_{xy}, D_{xy}) \) of the pier skeleton curve approximately corresponds to the state when the outermost spring on the compression side reaches the yield deformation \( d_{sy} \).

Eq. (1) is integrated with respect to the spring \( l \) as

\[
d_i = -\frac{R}{L} D_x \cos \theta_i + D_z
\]

Noting that \( d_i = d_s \), \( D_x = D_{xy} \), \( \cos \theta_i = 1 \) and \( D_z = -PL/(EA) \), the yield point of the compression side is given by

\[
d_{sy} = -\frac{R}{L} D_{xy} \frac{PL}{EA}
\]

\[
f_{sy} = k_{se} d_{sy}
\]

The three parameters: \( d_{sy} \), \( k_{sh} \) (or \( f_{sy} \)) and \( k_{sd} \) are determined by a trial and error method. If we assume reasonable values for these three parameters, we can calculate a monotonic loading curve as shown in Fig.8 by the multiple spring model. \( y \) is the yield point and \( m \) is the peak point of the tri-linear skeleton curve of the 2-parameter model. \( m \$s$ is the peak point obtained by the multiple spring model. The pier under deformation of \( D_{xy} \) is in a state where the pier exhibits a steady softening behavior. In this state, the compressive springs are in the fully softening state and the tensile springs are in the fully plastic state. We will determine the set of values \( d_{se} \), \( k_{se} \) and \( k_{sd} \) so that the point \( m \$s$ and the final descending line stiffness \( K_{ds} \) matches with the point \( m \) and \( K_d \), respectively.

At the fully softening stage when \( D_x = D_{xy} \), \( K_{ds} \) is only governed by \( k_{sd} \). Thus, the value of \( k_{sd} \) is first determined. In determining \( k_{sd} \) what is needed for \( d_{se} \) and \( k_{se} \) is just to give them a set of reasonable values, not exact values. The following
equations are used to predict the reasonable values.

\[ d_{ca} = \frac{R}{L} D_{xm} \]  

(40)

\[ k_{ch} = \frac{k_{ce}}{2} \]  

(41)

Eq. (40) corresponds to the displacement of the outermost springs when the horizontal displacement at the top of the pier reaches \( D_{xm} \), while, just as a reasonable value, the effect of constant vertical force \( P \) on horizontal displacement is neglected. As shown in Eq. (41), half of the initial elastic stiffness \( k_{ce} \) is given to \( k_{ch} \) as a reasonable value. Once reasonable values are given to \( d_{ca} \) and \( k_{ch} \), \( k_{ca} \) is determined by the usual bisection method.

If we express the range of \( k_{ce} \) as \( k_{cai} < k_{ce} < k_{ca} \), the limiting values for the bisection method can be assumed as

\[ k_{cai} = C_1 \]  

(42)

\[ k_{ca} = 0 \]  

(43)

where \( C_1 \) is a big negative value.

Secondly, the two parameters, point \( C_m (d_{ca}, f_{ca}) \) or \( (d_{ca}, k_{ch}) \) can also be determined by the bisection method for two variables. Herein, \( d_{ca} \) and \( k_{ch} \) are selected as these two variables to be identified. Since a particular technique is included in the bisection method for two variables, the method is explained in some detail.

The ranges for the two parameters are denoted here as \( d_{cai} < d_{ca} < d_{ca} \) and \( k_{chi} < k_{ch} < k_{ch} \). The initial value for \( d_{ca} \) can be given as

\[ d_{ca} = \frac{R}{L} D_{xm} \frac{PI}{EA} \]  

(44)

where \( \xi \) is a constant that reflects the effect of plastification on the axial deformation. It is found that \( \xi = 2. \) is acceptable in analyses.

If we use \( d_{ca} \) given by Eq. (44) as \( d_{ca} \) in the skeleton curve of the spring model, the outermost spring on compression side of the multiple spring model starts to enter the descending line when the horizontal displacement approaches \( D_{xm} \). Under this displacement, however, the rest of the springs on the compression side are still in the hardening stage. Therefore, under \( D_{xm} \), the peak point \( m_{si} \) for the multiple spring model is not reached yet. This implies that \( D_{xm} > D_{xm} \). As can be seen from Fig. 9, if we adopt \( d_{ca} \) that satisfies the relation

\[ D_{xm} > D_{xm} \]  

it is possible to determine the value of \( k_{ch} \) that ensures \( F_{xm} = F_{xm} \). So, in the two-variable bi-section method, we can choose \( d_{ca} \) as an initial value of \( d_{ca} \) and increase \( d_{ca} \) with a small step increment with keeping \( F_{xm} = F_{xm} \) until \( D_{xm} < D_{xm} \) is satisfied. The trial value of \( d_{ca} \) in the \( i \)-th iterative process is given as

\[ d^{(i)} = d_{ca} + i \Delta d_{ca} \]  

(45)

where \( \Delta d_{ca} \) can be set as

\[ \Delta d_{ca} = -0.005 d_{ca} \]  

(46)

For a given \( d_{ca}^{(i)} \), the usual bisection iterative method is used to determine a corresponding hardening stiffness \( k_{ch(i)} \). The initial range for \( k_{chi} \) may be assumed as

\[ k_{chi} = 0 \]  

(47)

\[ k_{ch(i)} = k_{ch} \]  

(48)

The trial value for the \( j \)-th iterative process for \( k_{ch(i)} \)
Fig. 10 Stiffness degradation and shrinkage of elastic range in spring model

\[ k^{(i)}_{ch(i)} = \frac{k_{ch(i)} + k_{shr(i)}}{2} \]  \hfill (49)

With the parameters so assumed, point \( ms(D_{x(m)}, F_{x(m)}) \) can be calculated by the multiple spring model. If \( F_{x(m)}^{(i)} > F_{x(m)} \), then we set \( k_{ch(i)} = k_{ch(i)}^{(i)} \). Otherwise, \( k_{shr(i)} = k_{shr(i)}^{(i)} \). This iterative process for a given \( d_{x(m)}^{(i)} \) is continued until the following tolerance is satisfied

\[ \frac{|F_{x(m)}^{(i)} - F_{x(m)}|}{|F_{x(m)}|} \leq \varepsilon_3 \]  \hfill (50)

After the optimum value of \( k_{ch} \) is obtained for \( d_{x(m)}^{(i)} \), we proceed to identify the optimum value of \( k_{ch} \) for the \( d_{x(m)}^{(i+1)} \) given by Eq. (45).

The above process is repeated until \( D_{x(m)} < D_{x(m)} \) is first satisfied for \( d_{x(m)}^{(i+1)} \). Then, we can identify the range for \( d_{x(m)} \) as

\[ d_{x(m)} = d_{x(m)}^{(i)} \]  \hfill (51)

\[ d_{x(m)} = d_{x(m)}^{(i+1)} \]  \hfill (52)

Once the range of \( d_{x(m)} \) is identified, the next trial value \( d_{x(m)}^{(i+2)} \) is given by the usual bi-section method instead of Eq. (45) as

\[ d_{x(m)}^{(i+2)} = \frac{d_{x(m)} + d_{x(m)}}{2} \]  \hfill (53)

After the optimum value of \( k_{ch} \) is obtained for the given \( d_{x(m)}^{(i+2)} \), \( D_{x(m)}^{(i+2)} \) is calculated by using \( k_{ch} \) and \( d_{x(m)}^{(i+2)} \). The optimum value of \( d_{x(m)} \) is determined by the condition that the following tolerance is satisfied

\[ \frac{|D_{x(m)}^{(i+2)} - D_{x(m)}|}{D_{x(m)}} \leq \varepsilon_4 \]  \hfill (54)

Finally, the skeleton curve on the compression side is determined as

\[ f = \begin{cases} k_{ch}d, & (d_{c} \leq d \leq 0) \\ f_{x} + k_{ch}(d - d_{c}), & (d_{c} < d < d_{c}) \\ f_{x} + k_{ch}(d - d_{c}), & (d \leq d_{c}) \end{cases} \]  \hfill (55)

(4) Hysteresis rule

The hysteresis rule of the spring model is divided into two parts, that is, the compression side and the tension side.

Regarding the rule on the compression side, the one similar to the 2-parameter model is utilized. This is because the skeleton curve of the spring model on the compression side is represented by the tri-linear curve given by the 2-parameter model. The hysteretic behavior of the 2-parameter model are characterized by the three rules: 1) the whole loading history is divided into two stages to consider the cyclic hardening effect; 2) the accumulated hysteretic energy of pier is used to predict the stiffness degradation; 3) the maximum deformation is used as an index to consider the strength degradation.

Regarding the hysteretic rule on the tension side, however, the skeleton curve of the spring model is
expressed by a bi-linear curve without descending line, being different from the 2-parameter model. Therefore, we adopt the kinematic hardening rule on the tension side and the hardening rule with negative stiffness on the compression side. The details of these rules are explained below.

Following the original 2-parameter model, the loading history of the spring model on the compression side is classified into two stages: hardening stage and unloading stage. Hardening stage is defined by the condition that the deformation of a spring \( d \) is within the range specified by \( d_{sc} \leq d \). \( d_{sc} \) is the displacement at the peak point of the skeleton curve on the compression side. In this stage, the behavior of spring is characterized by the cyclic hardening behavior where the elastic range and the stiffness is stay constant. Once the displacement passes \( d_{sc} \), then the spring moves into the unloading stage. The hysteretic behavior in the unloading stage is characterized by the deterioration of the elastic stiffness \( k \) and the shrinkage of elastic range \( 2f_y' \), as illustrated in Fig.10.

As for the degradation rule for elastic stiffness \( k \), the idea of the 2-parameter model is used for each spring. In the degradation stage, stiffness degradation occurs, whenever unloading occurs. The degraded elastic stiffness \( k \) is assumed to be governed as follows by the accumulated hysteretic energy of the springs. \[ k_{cr} = k \left( \frac{1}{\alpha} \ln \left( \frac{\sum E_i}{E_s} + 1 \right) \right) = g \left( \sum E_i \right) \] (56)
where \( \alpha = 1/(7.36R_e) \) according to the 2-parameter model. Although the shapes of skeleton curves on the tension side and compression side are different, we use the same value for the empirical parameter \( \alpha \).

With the use of the degraded elastic stiffness \( k \) calculated by Eq. (56), the shrinked elastic range \( 2f_y' \) is assumed to be given by \[ 2f_y' = k(d_{ty} + d_{cy}) \] (57)
where \( d_{ty} \) and \( d_{cy} \) denote yield displacements of the skeleton curve on the tension side and the compression side, respectively. The above equation implies that the elastic range shrinks in proportion to the elastic stiffness.

In what follows, two important loading histories are chosen to explain the hysteretic rules. The first one represents the loading history in the hardening stage, while the second one represents the loading history in the unloading stage.

**Fig.11(a)** illustrates the hysteretic rule when the spring is in the hardening stage and the unloading first occurs on the compression side. At this stage the cyclic hardening effect is the major characteristics of the hysteretic behavior. Starting from point \( O \), the initial yielding occurs at point \( A \). Then, the loading point follows a hardening line heading to the peak point \( c_m (d_{cm}, f_{cm}) \). Suppose that unloading occurs at point \( B \) on the hardening line and this unloading is followed by reverse loading. The loading point goes to the yield point \( C \) on the tension side with the elastic stiffness of \( k_{w} \) that is the same as the initial elastic stiffness. In the hardening stage, the kinematic hardening model is used and the elastic range \( 2f_y' \) remains constant as given by
\[ 2f_y' = f_y + f_c \] (58)

where \( f_y \) and \( f_c \) denote yield forces of the skeleton curve on tension side and compression side, respectively. Beyond point \( C \), the loading point follows the hardening line that is parallel to the initial skeleton curve where the stiffness of the hardening line on the tension side keeps the initial value \( k_{w} \). If unloading occurs at point \( D \), the loading point heads to the yield point \( F \), where both the elastic stiffness \( k \) and the elastic range \( 2f_y' \) keep the initial values. After point \( F \) the loading point will again follows a hardening line heading to the peak point \( c_m (d_{cm}, f_{cm}) \).

**Fig.11(b)** shows the case when the first unloading occurs at point \( A \) in the degradation range on the compression side. From point \( A \), the loading point goes to the yield point \( B \) under unloading and subsequent reverse loading. Since the loading point is in the degradation range, the elastic stiffness \( k \) decreases and the elastic range \( 2f_y' \) shrinks, depending on the hysteretic energy \( E_i \), as respectively given by Eqs. (56) and (57). After point \( B \) is reached, the loading point follows a hardening line that is parallel to the skeleton curve with the stiffness of \( k_{w} \). When unloading occurs at point \( C \), loading point goes to the yield point \( D \) under reverse loading. In this elastic stage, the elastic stiffness and the elastic range are governed by the accumulated hysteretic energy \( E_i + E_s \). After point \( D \) is reached, the loading point heads to point \( F \) that is on the skeleton curve with the deformation of \( d_{emax} \cdot d_{cm} \)

denotes the maximum deformation that the spring has ever experienced on the compression side.

The validity of the present hysteretic rules is examined in the next section, by comparing the hysteretic curves of steel piers obtained by the multiple spring model with those by the 2-parameter model.

4. COMPARISONS WITH THE OTHER MODELS

(1) In-plane hysteretic behavior

Herein, we examine the accuracy of the multiple spring model by comparing with 2-parameter model. For this purpose, three pier models with different
Fig. 12  Homogeneity of multiple spring model expressed in terms of horizontal force $F_n$-horizontal displacement $D_n$ relation (pier 1)

Fig. 13  Comparison between multiple spring model and 2-parameter model
governing parameters shown in Table 1 are used as numerical examples. Since the 2-parameter model is applicable for thin-walled circular steel piers with $0.07 \leq R_i \leq 0.11$, pier 1 with $R_i = 0.07$ and pier 2 with $R_i = 0.11$ are adopted here to cover the applicable range for $R_i$. The other two governing parameters $\lambda$ and $\mu$ are changed for pier 3 with keeping $R_i = 0.07$.

First, the parameters for the skeleton curves of the springs are identified following the procedure explained in section 3 based on the 2-parameter model. Parameters of the skeleton curves so identified are summarized in Table 2. The number of springs, that is 32, is determined by considering homogeneous behavior of steel piers in any horizontal directions. In Fig.12, it is shown how the horizontal force-horizontal displacement relation of pier 1 becomes homogeneous by increasing the number of springs. From this figure, it is observed that 16 springs are enough to ensure the homogeneity. Herein, 32 springs are used by taking into account of the homogeneous behavior of pier 2 and pier 3.

In Fig.13, the multiple spring model is compared with the 2-parameter model for three pier models in terms of the in-plane skeleton curves and hysteretic behaviors. It is observed from Fig.13(a) that the multiple spring model shows acceptable accuracy to express the in-plane skeleton curves of the 2-parameter model. However, some difference exists in the cyclic behavior in the post-peak range. This difference is more evident for pier 2 with a larger value of $R_i$ where the deterioration is strongly affected by the local buckling. There still remains some room to improve the hysteretic rule for thinner circular steel piers.

(2) 3-D dynamic response

In the three-dimensional dynamic response analyses, the accuracy of the multiple spring model is examined in comparison with the 3-D FEM dynamic analysis using shell element where the local buckling behavior is precisely considered. Piers shown in Table 1 with different values of $R_i$ are chosen for these analyses. The FEM analysis using shell elements is carried by ABAQUS[10]. The pier model used for the FEM analysis is illustrated in Fig.14. The thick shell element S4R is chosen as the element type in the whole cylinder. The very fine mesh division is used especially near the pier base where large localized deformation is expected to occur. As the constitutive model to express the cyclic plasticity of steel, the three-surface model[11] is implemented in ABAQUS by using the user defined subroutine feature. The material constants of the three-surface model are given in Table 3.

Regarding the multiple spring model, number of springs used in the present analysis is the same as that in the previous sub-section 4. (1). For pier 1, two kinds of earthquake waves recorded in the 1995 Kobe Earthquake are applied. One is the HKB (Higashi Kobe Bridge) acceleration wave where $L-G$, $T-R$ and $U-D$ components are assumed to be respectively coincident with $X$, $Y$ and $Z$ components. The other is the JMA (Japan Meteorological Agency) acceleration wave where $E-W$, $N-S$ and $U-D$ components are used as $X$, $Y$ and $Z$ direction. In the analysis of pier 2 and pier 3, only the JMA record is considered. The integration time step used in the 3-D earthquake response analysis is set as 0.005 second for JMA wave and 0.01 second for HKB wave. In Table 4, the multiple spring model is compared with the FEM shell model in view of the computational efficiency. It can be seen from Table 4 that the computation time is drastically shortened by the multiple spring model.

The results of the earthquake response analysis obtained by the multiple-spring model are summarized in Figs.15–24, in comparison with those obtained by the FEM analysis. Figs.15–18 show the sway displacement response histories of piers and Figs.19–22 illustrate the sway-displacement trajectories. Fig.24 shows the final deformation patterns of pier models obtained by FEM analysis. From this figure, local buckling patterns are observed in all piers. Among the three piers, pier 3 with the largest radius-to-thickness ratio exhibits the largest localized deformation. This large localized
deformation may lead to some discrepancy between the FEM shell model and the multiple spring model in the horizontal response displacement of pier 3, as can be seen from Figs.13(b), 18 and 22. Except for the error caused by highly localized deformation, it is observed from Figs.15–18 and Figs.19–22 that the proposed multiple spring model can be an acceptable alternative to the FEM shell model in practical design as long as the localized deformation is moderate and not extremely large.

Regarding the vertical response of piers, the results obtained by the multiple spring model are
very different from those obtained by the FEM analysis as shown in Fig. 23. One reason for this difference is that the constitutive relation for springs is calibrated not by the vertical displacement but by the horizontal displacement at the top of the pier. The other reason is that the magnitude of the vertical displacement is much smaller than that of the horizontal displacement. However, the vertical displacement predicted by the multiple spring model may have little effects practically because the vertical behavior is usually ignored in seismic design.

The residual displacement calculated by the multiple spring model also tends to be somewhat different from that by FEM analysis. This is because the residual displacement is very sensitive to the numerical errors and even small errors have a big influence on the final displacement.
5. CONCLUSIONS

In view of the application to the practical design, a multiple spring model is proposed to express the 3D-hysteretic behavior of moderately thin-walled piers. The model consists of a rigid pier and multiple nonlinear springs located at the pier base. These multiple springs can represent not only the interaction between the axial force and the biaxial
bending but also the local buckling effect. The constitutive relation for each spring is expressed by the multi-linear model and the parameters of this model are calibrated based on the in-plane hysteretic behavior of the 2-parameter model. In order to show the validity of the proposed model, 3-D earthquake response analyses are carried out by using both the multiple spring model and the FEM shell model. The results showed that the multiple spring model can be an acceptable alternative to the costly FEM shell analysis as long as the localized deformation is moderate and not extremely large. Furthermore, the computation time of the multiple spring model in the 3-D dynamic response analyses is drastically reduced to 1/5000 ~ 1/6000 of the computation time of the FEM shell model.
